

Example:

Definition (Ranked alphabet,  $\Sigma$ -trees)

A ranked alphabet is a

finite set  $\Sigma$

together with a rank function  $rk: \Sigma \rightarrow \mathbb{N}$ .

Call

$rk(a) =$  rank of letter  $a$

Intuitively:

•  $a$  expects  $rk(a)$  children

• similar to arity of function / predicate symbols

A  $\Sigma$ -tree is a function

$t: T \rightarrow \Sigma$

where  $T$  is a finite tree as above.

Moreover, for all  $w \in T$  and all  $a \in \Sigma$  with  $rk(a) = n$ ,

$t$  satisfies  $w.i \in T$  iff  $i \in \{1, \dots, n\}$  f.o.  $i \in \mathbb{N}$ .

// If  $w$  is labelled by  $a$  then  $w$  has precisely  $rk(a)$  children.

Let  $\Sigma_n = \{a \in \Sigma \mid rk(a) = n\}$

Moreover,  $\mathcal{T}_\Sigma =$  set of all  $\Sigma$ -trees.

### Note:

- Impossible to find two nodes with same label but different number of children
- Alphabet gives upper bound on number of children in a tree.

### Example:

Let  $\Sigma = \{+, /, *, \cdot, -, 0, 1\}$   
a ranked alphabet.

Arithmetic expression

$$-(7 * 3) + (-4 + 9)$$

in binary encoding can be represented by

For the exercises: the yield of a tree

Read word consisting of letters on the leaves.

Let  $t: T \rightarrow \Sigma$  a tree.

Its yield is defined inductively:

If  $T = \{\epsilon\}$  then  $\text{yield}(t) := t(\epsilon)$ .

Otherwise,  $t$  has subtrees  $t_0, \dots, t_n$ .

Let

$$T = \{ \epsilon \} \cup 0.T_0 \cup \dots \cup n.T_n.$$

Define

$$t_i : T_i \rightarrow \Sigma \quad \text{by} \quad t_i(w) = t(i.w) \quad \text{f.o.} \quad 0 \leq i \leq n.$$

With this

$$\text{yield}(T) := \text{yield}(t_0) \dots \text{yield}(t_n).$$

Example:

$\text{yield} \left( \begin{array}{c} \textcircled{S} \\ \swarrow \quad \downarrow \quad \searrow \\ \textcircled{a} \quad \textcircled{S} \quad \textcircled{b} \\ \swarrow \quad \downarrow \quad \searrow \\ \textcircled{a} \quad \textcircled{T} \quad \textcircled{b} \\ \downarrow \\ \textcircled{c} \end{array} \right) = \text{aacbb}.$

Apply the definition:

$$\begin{aligned} \text{yield} \left( \begin{array}{c} \textcircled{S} \\ \swarrow \quad \downarrow \quad \searrow \\ \textcircled{a} \quad \textcircled{S} \quad \textcircled{b} \\ \swarrow \quad \downarrow \quad \searrow \\ \textcircled{a} \quad \textcircled{T} \quad \textcircled{b} \\ \downarrow \\ \textcircled{c} \end{array} \right) &= \text{yield}(\textcircled{a}) \cdot \text{yield} \left( \begin{array}{c} \textcircled{S} \\ \swarrow \quad \downarrow \quad \searrow \\ \textcircled{a} \quad \textcircled{T} \quad \textcircled{b} \\ \downarrow \\ \textcircled{c} \end{array} \right) \cdot \text{yield}(\textcircled{b}) \\ &= a \cdot \text{yield}(\textcircled{a}) \cdot \text{yield}(\textcircled{T}) \cdot \text{yield}(\textcircled{b}) \cdot b \\ &= a \cdot a \cdot \text{yield}(\textcircled{c}) \cdot b \cdot b \\ &= \text{aacbb}. \end{aligned}$$

Two different automaton models for trees:

- ↳ Finite automata read words from left to right
- ↳ Theory would not change if they read words from right to left.
- ↳ Trees look different when read from top to bottom vs. bottom up.

## Difference:

- From top to bottom distribute information from one node to many
- Bottom-up aggregates information from children.  
=> yields different theories.

## Definition (Bottom-up tree automaton)

A bottom-up tree automaton (BUTA) over  $\Sigma$  is a tuple

$$A = (Q, \rightarrow, Q_f)$$

with

- set of states  $Q$  (finite)
- transition relation  $\rightarrow = (\rightarrow_a)_{a \in \Sigma}$  with  
 $\rightarrow_a \subseteq Q^n \times Q$  where  $n = r_h(a)$ .
- set of final states  $Q_f \subseteq Q$ .

A run of a BUTA labels nodes of a tree by states

- ↳ starting at the leaves
  - ↳ stopping at the root
  - ↳ transitions read states of (root of) subtrees
- } bottom-up.

No initial state:

- ↳ encoded into transition relation for  $a$  with  $r_h(a) = 0$ .
- ↳ Define  $\rightarrow_a \subseteq Q^0 \times Q$  as  $\rightarrow_a \subseteq Q$ .
- ↳ This means initial state chosen according to leaf letter
- ↳ Slight difference when compared to finite automata  
=> can always extend finite automata by one state to achieve this effect.

Definition (Accepting) run, tree language:

A run of BUTT  $\mathcal{A} = (Q, \rightarrow, Q_F)$  on a  $\Sigma$ -tree  $t: T \rightarrow \Sigma$  is a function

$$r: T \rightarrow Q$$

so that for all  $w \in T$  we have

$$\begin{array}{ccc} (r(w.0), \dots, r(w.(n-1))) & \rightarrow_a & r(w) \\ \begin{array}{ccc} \text{"} & & \text{"} \\ q_0 & & q_{n-1} \end{array} & & q \end{array}$$

where  $a = t(w)$  and  $n = r(w)$ .

A run is accepting if  $r(\epsilon) \in Q_F$ .

Then  $\mathcal{L}(\mathcal{A}) \subseteq \mathcal{T}_\Sigma$  is the (tree) language of  $\mathcal{A}$ :

$$\mathcal{L}(\mathcal{A}) := \{ t \in \mathcal{T}_\Sigma \mid \mathcal{A} \text{ has an accepting run on } t \}.$$

(all the class of tree languages that can be accepted by BUTT the regular tree languages.)

Example:

Let  $\Sigma = \{ \vee/2, \wedge/2, \neg/1, \epsilon/0, f/0 \}$

• It allows us to encode all variable-free Boolean expressions as trees.

• Language of all expressions that evaluate to true is accepted by following BUTT:

$$\mathcal{A} = (\{q_0, q_1\}, \rightarrow, \{q_1\})$$

with

$$\begin{array}{cccc} \rightarrow_f q_0 & q_0 \rightarrow_{\neg} q_1 & (q_0, q_0) \rightarrow_{\vee} q_0 & (q_0, q_0) \rightarrow_{\wedge} q_0 \\ \rightarrow_{\epsilon} q_1 & q_1 \rightarrow_{\neg} q_0 & (q_0, q_1) \rightarrow_{\vee} q_1 & \dots \\ & & \dots & (q_1, q_1) \rightarrow_{\wedge} q_1. \end{array}$$

Note that this BUTT is deterministic.

Consider

Run is accepting since

$$r(\epsilon) = q_1 \in Q_f = \{q_1\}.$$

Definition (Deterministic BUTM):

A BUTM  $M = (Q, \rightarrow, Q_f)$  is called deterministic (DBUTM) if for all  $a \in \Sigma$  and all  $(q_0, \dots, q_{n-1}) \in Q^n$  with  $n = r_h(a)$  we have precisely one  $q \in Q$  so that

$$(q_0, \dots, q_{n-1}) \xrightarrow{a} q.$$

Are deterministic BUTM as powerful as non-deterministic BUTM?

↳ Yes, apply powerset construction.

Theorem:

A language is accepted by a BUTM iff it is accepted by a DBUTM.

Proof:

⇐ By definition

⇒ Let  $L = L(M)$  with  $M = (Q^M, \rightarrow^M, Q_f^M)$ .

Construct

$$M' := (P(Q^M), \rightarrow, Q_f)$$

with

$$Q_f := \{Q \subseteq Q^M \mid Q \cap Q_f^M \neq \emptyset\}$$

and

$$(Q_0, \dots, Q_{n-1}) \xrightarrow{a} Q \text{ where}$$

$$Q = \{q \in Q^M \mid \text{there are } q_0 \in Q_0, \dots, q_{n-1} \in Q_{n-1}$$

with  $n = r_h(a)$ .

so that  $(q_0, \dots, q_{n-1}) \xrightarrow{a} q \in Q_f^M$

□

It's a consequence, regular tree languages closed under complementation.

Lemma:

Let  $\mathcal{A}$  a DBUTA accepting  $L$ .

Then there is a DBUTA  $\overline{\mathcal{A}}$  accepting  $\overline{L}$ .

Proof:

Swap final and non-final states.

If  $\mathcal{A} = (Q, \rightarrow, Q_f)$ , set  $\overline{\mathcal{A}} = (Q, \rightarrow, Q \setminus Q_f)$ .

Regular tree languages also closed under union. □

Second possibility of reading trees: top-down.

Definition (Top-down tree automata):

$\mathcal{A}$  top-down tree automaton (TDTA) over  $\Sigma$

is a tuple  $\mathcal{A} = (Q, q_0, \rightarrow)$  with

- set of states  $Q$  (finite)
- initial state  $q_0 \in Q$
- transition relation  $\rightarrow = (\rightarrow_a)_{a \in \Sigma}$  with  
 $\rightarrow_a \subseteq Q \times Q^n$  with  $n = r_k(a)$ .

A TDTA  $\mathcal{A}$  is called deterministic (DTDTA)

if for all  $a \in \Sigma$  and all  $q \in Q$  there is

precisely one vector  $(q_0, \dots, q_{n-1}) \in Q^n$  with  $n = r_k(a)$

so that

$$q \rightarrow_a (q_0, \dots, q_{n-1}).$$

Definition (Run of TDTA, language):

A run of a TDTA  $\mathcal{A} = (Q, q_0, \rightarrow)$  on a  $\Sigma$ -tree  $t: T \rightarrow \Sigma$

is a function

$$r: T \rightarrow Q$$

with

$$r(\varepsilon) = q_0 \text{ and } r(w) \rightarrow_a (r(w.0), \dots, r(w.n-1)) \text{ f.o. } w \in T$$

with  $a = t(w)$  and  $n = r_k(a)$ .

Then

$L(A) := \{ t \in \Sigma^* \mid \text{there is a run } r \text{ of } A \text{ on } t \}$ .

There are no final states:

$\hookrightarrow$  Modelled by the fact that

$r(w) \rightarrow a()$  defined by  $r(w) \in Q \times Q^0$ .

(Vs. non existence of such a transition).

Example:

Let  $\Sigma = \{ a/2, b/2, c/0 \}$

• Consider language of all trees that contain at least one  $b$ .

•  $L$  is TDITA acceptable by

$A = (\{ q_-, q_+ \}, q_-, \rightarrow)$

with

$q_+ \rightarrow a(q_+, q_+)$

$q_- \rightarrow a(q_+, q_-)$

$q_+ \rightarrow b(q_+, q_+)$

$q_- \rightarrow a(q_-, q_+)$

$q_+ \rightarrow c$

$q_- \rightarrow b(q_+, q_+)$

Intuition:

$q_-$  = still need to find a "b"

$q_+$  = have already seen a "b" somewhere.
